

A PROJECT REPORT ON

**DESIGN AND IMPLEMENTATION OF SOLAR-POWERED
DEWATERING IN MINING OPERATIONS**

An IoT-Based Automated Water-Level Sensing and Pump Control System for Sustainable Mine Dewatering

Submitted in partial fulfilment of the requirements for the mini-project / academic project component

Department of Electronics and Communication Engineering

2026

Abstract

Water accumulation in open-pit and underground mines is a persistent operational hazard that threatens equipment, worker safety, and production continuity. Conventional dewatering systems rely on grid-powered pumps that run continuously irrespective of actual water levels, resulting in high energy consumption and increased operating costs, particularly in remote mining sites with unreliable grid access. This report presents the design and implementation of a solar-powered, sensor-driven dewatering system that automatically detects rising water levels in a mine sump and activates a pump only when required.

The system integrates an ultrasonic distance sensor and an analog water-level sensor with a microcontroller unit (ESP32) that processes sensor data, displays real-time status on an SSD1306 OLED display, and switches a relay-controlled DC motor pump to remove accumulated water. A solar panel and rechargeable battery bank power the entire system, making it suitable for deployment in off-grid or remote mining locations. A working prototype was built and tested, demonstrating reliable automatic pump activation, water-level monitoring, and reduced energy wastage compared to continuously-running pump systems.

Testing on a scaled-down prototype confirmed that the relay reliably switches the motor pump within a fraction of a second of the water level crossing the configured analog threshold, and that the OLED display and serial console consistently report the sampled water level for on-site diagnostics. The results confirm that solar-powered automated dewatering is a viable, low-cost, and energy-efficient solution for small to medium-scale mining operations, and that the architecture can be scaled to larger pump capacities and sump volumes with minimal redesign.

Keywords: Solar-powered dewatering, ESP32, water-level sensor, relay automation, OLED display, sustainable mining, IoT, renewable energy.

1. Introduction

Mining is one of the oldest and most resource-intensive industrial activities, and it is almost universally accompanied by the challenge of water ingress. Whether from groundwater seepage, rainfall runoff, or process water, accumulated water inside a pit, shaft, or underground gallery interferes with excavation, damages machinery, destabilizes slopes, and creates serious safety hazards for personnel and equipment. Dewatering, the systematic removal of this water, is therefore not an optional convenience but a core operational requirement for almost every mine, irrespective of its scale.

Historically, dewatering has been achieved using diesel-powered or grid-connected electric pumps that are switched on according to a fixed schedule or left running continuously as a precaution. Both approaches waste a significant amount of energy: fixed schedules do not account for actual rainfall or seepage variability, and continuous operation wastes fuel or electricity during periods when little or no water is present. In many developing regions and remote extraction sites, grid electricity is either unavailable or unreliable, forcing operators to depend on diesel generators, which are expensive to run and have a considerable carbon footprint.

Two converging trends motivate the work presented in this report. First, the falling cost and improving efficiency of photovoltaic solar panels and battery storage have made solar power a practical primary energy source for small and medium loads in remote locations. Second, the wide availability of inexpensive, capable microcontroller platforms such as the ESP32, combined with low-cost sensors, has made it feasible to build intelligent, sensor-driven automation for tasks that were previously handled manually or with simple timer-based control.

This project combines both trends to design a solar-powered, automatic dewatering system: a system that senses the water level in a sump using an analog water-level sensor (supplemented conceptually by an ultrasonic sensor for non-contact ranging), decides whether pumping is required, and switches a DC motor pump on or off accordingly through a relay, while displaying live status on an OLED screen. The complete electronic load is powered from a solar-charged battery bank, removing the dependency on grid power or diesel fuel altogether.

This report documents the complete design and implementation process: the problem motivating the work, a review of related approaches, the system architecture, the hardware and software design, the testing methodology and results, a cost estimation, and a discussion of the advantages, limitations, and possible directions for future improvement.

2. Literature Survey

A number of prior works and industrial practices inform the design choices made in this project. This chapter briefly reviews four related areas: conventional mine dewatering practice, sensor-based automatic water-level control, solar-powered pumping systems, and microcontroller-based IoT monitoring.

2.1 Conventional Mine Dewatering Practice

Industry dewatering practice typically relies on large submersible or surface centrifugal pumps sized for worst-case water inflow, powered by grid electricity or diesel generators. Pump operation is frequently controlled manually by site personnel, or by simple float switches that provide only on/off control without any data logging or remote visibility. While robust, these systems are energy-inefficient because they do not incorporate graduated, sensor-driven decision-making, and they provide little insight into water-level trends over time.

2.2 Sensor-Based Automatic Water-Level Control

Research into automatic water-level controllers for domestic, agricultural, and industrial tanks has demonstrated that combining a water-level sensor (resistive, capacitive, or ultrasonic) with a microcontroller and a relay-driven pump can reliably automate pump switching with a simple threshold-based algorithm. These systems are attractive because they are inexpensive, easy to replicate, and require minimal firmware complexity, while still delivering substantial energy savings relative to continuously-running pumps.

2.3 Solar-Powered Pumping Systems

Solar-powered water pumping is well established in irrigation and rural water-supply applications, where a photovoltaic array charges a battery bank that in turn powers a DC or AC motor pump, often through a charge controller and, in more advanced systems, a maximum power point tracking (MPPT) converter. Literature in this space consistently reports that correctly sized solar-battery systems can reliably sustain small to medium pump loads in areas with reasonable daily solar insolation, provided the battery bank is sized to bridge low-sunlight periods.

2.4 Microcontroller-Based IoT Monitoring

The ESP32 and similar system-on-chip microcontrollers have become popular in monitoring and automation projects because they combine adequate processing power, a rich set of peripherals (I2C, SPI, ADC, PWM), and built-in Wi-Fi/Bluetooth connectivity, all on a low-cost, low-power module. Combined with small OLED displays such as the SSD1306, these boards allow a compact, self-contained monitoring and control unit to be built without a bulky control panel, and they can be extended with wireless connectivity for remote alerts or cloud logging.

2.5 Research Gap

While each of the four areas above has been individually well studied, there is comparatively little published work specifically combining solar power, low-cost sensor-driven automation, and OLED-based local status display for the specific context of mine sump dewatering. Most published sensor-based pump controllers

target domestic or agricultural water tanks rather than the harsher, more variable conditions of a mine sump. This project addresses that gap by adapting the general sensor-relay-pump automation pattern to the mine dewatering context and pairing it with a solar-battery power supply suitable for off-grid mine sites.

3. Problem Statement and Objectives

3.1 Problem Statement

Mining operations situated in remote or off-grid locations face significant challenges in maintaining continuous power supply for dewatering pumps. Manually operated or continuously running pumps waste energy, require constant human supervision, and increase operational costs. There is a need for an autonomous, energy-efficient dewatering system that senses water levels in real time and activates the pump only when necessary, while being powered entirely by renewable solar energy to eliminate dependency on the grid or diesel generators.

3.2 Objectives

- To design a low-cost, solar-powered automatic dewatering system for mining sumps and pits.
- To use a water-level sensor (and, conceptually, an ultrasonic sensor) for real-time water level detection.
- To automate pump activation and deactivation using a relay module controlled by a microcontroller.
- To display real-time water level status on an OLED screen for on-site monitoring.
- To power the complete system using solar panels and rechargeable batteries for off-grid operation.
- To reduce energy consumption and manual intervention compared to conventional dewatering pumps.
- To validate the design through a working prototype and document its performance.

3.3 Scope of the Project

The scope of this project covers the design, assembly, and bench-scale testing of a prototype system. Full-scale deployment considerations, such as sizing the pump and solar array for an actual mine sump, industrial-grade enclosures, and regulatory compliance, are discussed qualitatively but are outside the physical scope of the prototype built for this report.

4. System Design and Methodology

The proposed system follows a sense-process-actuate architecture, a common pattern in embedded control systems. Water level information is first sensed, then processed by a decision-making unit, and finally used to actuate a physical output, in this case a motor pump. This chapter describes the overall methodology and block-level design before the following chapters detail the hardware and software individually.

4.1 Design Approach

The design process followed four broad stages. First, the functional requirements were identified: automatic sensing of water level, automatic control of a pump, local visual status indication, and fully off-grid power. Second, suitable low-cost components were selected for each function, favouring widely available modules to keep the system replicable and affordable. Third, the components were wired together and a firmware program was written to implement the sensing and control logic. Fourth, the assembled prototype was tested under simulated conditions to validate correct operation before documenting the results.

4.2 System Block Diagram

At the block level, the system consists of five functional groups: the sensing block, the processing block, the display block, the actuation block, and the power block. The sensing block (water-level sensor, and conceptually an ultrasonic sensor) continuously reports water level information to the processing block. The processing block (ESP32 microcontroller) reads the sensor, applies the control logic, and drives both the display block (SSD1306 OLED) and the actuation block (relay module and DC motor pump). The power block (solar panel, battery, and voltage regulation) supplies stable power to every other block.

[Solar Panel] -> [Battery + Regulator] -> powers -> { Sensors, ESP32, OLED, Relay, Pump } [Solar Panel] -> [Battery + Regulator] -> powers -> { Sensors, ESP32, OLED, Relay, Pump }

Fig. 3 - System Block Diagram (textual representation)

4.3 Design Considerations

- Low power consumption to keep the solar-battery supply small and affordable.
- Simple, well-documented modules (ESP32, SSD1306, single-channel relay) to keep replication straightforward.
- A threshold-based control algorithm that is easy to verify, calibrate, and adjust in the field.
- A local display for status visibility without requiring a network connection, while leaving room for future wireless extension.
- Modularity, so that the pump, sensor, or display can each be swapped or scaled independently.

5. Hardware Components

This chapter describes each hardware module used in the prototype, including its role in the system and its key specifications. Table 1 summarises the complete component list, followed by individual subsections describing the most important modules in more detail.

#	Component	Function	Typical Rating
1	ESP32 Dev Board	Main processing/control unit	Dual-core, 240 MHz, 3.3 V logic
2	Water Level Sensor	Analog detection of water presence/level	0-3.3 V analog output
3	Ultrasonic Sensor (HC-SR04)	Non-contact distance/level sensing	2-400 cm range, 5 V
4	1-Channel Relay Module	Switches motor pump under microcontroller control	5 V coil, 10 A contact
5	DC Submersible Motor Pump	Removes accumulated water	3-6 V DC, small flow rate
6	SSD1306 OLED Display	Shows real-time status	128x64 px, I2C interface
7	Buzzer	Audible alert on threshold breach	5 V piezo buzzer
8	Solar Panel	Renewable energy source	5-10 W, 6-12 V
9	Li-ion Battery Pack	Energy storage for off-grid operation	2x 3.7 V cells (series/parallel)
10	Voltage Regulator / Charging Module	Regulates and manages charge/discharge	TP4056 / similar

Table 1 - Component List and Specifications

5.1 ESP32 Development Board

The ESP32 is a low-cost, low-power system-on-chip with integrated Wi-Fi and Bluetooth, a dual-core processor running up to 240 MHz, and a rich set of peripherals including multiple ADC channels, I2C, SPI, and PWM-capable GPIO pins. In this project, the ESP32 reads the analog water-level sensor on an ADC-capable pin, drives the relay module through a digital output pin, and communicates with the OLED display over the I2C bus. Its low idle power consumption makes it well suited to a battery-and-solar power budget.

5.2 Water Level Sensor

The water-level sensor used in the prototype is a simple resistive-trace sensor: a set of parallel exposed copper traces that change conductivity depending on how much of the sensor is submerged. As water rises and bridges more traces, the analog output rises proportionally, giving the microcontroller a graduated reading rather than a simple on/off signal. This sensor was chosen for its low cost, simple analog interface, and ease of calibration.

5.3 Ultrasonic Sensor (HC-SR04)

The HC-SR04 ultrasonic sensor measures distance by emitting an ultrasonic pulse and timing the echo return. In the full system design, this sensor is mounted above the sump to provide a non-contact measurement of the water surface distance, which is useful for larger sumps or where a submerged sensor is impractical or subject to fouling. It complements the contact-based water-level sensor by providing an independent, non-contact measurement channel.

5.4 Relay Module

The single-channel relay module provides the interface between the low-power digital output of the ESP32 and the higher-current DC motor pump. The relay used in this design is an active-low module: a LOW signal on its control input energizes the relay coil and closes the contacts (turning the pump ON), while a HIGH signal de-energizes the coil (turning the pump OFF). This detail is important for correctly interpreting the firmware logic described in Chapter 7.

5.5 DC Motor Pump

A small submersible DC motor pump was used to physically remove water from the simulated sump during testing. In a full-scale deployment, this component would be replaced by a pump sized for the expected inflow rate and lift height of the actual mine sump, while the sensing and control electronics would remain largely unchanged.

5.6 OLED Display

The SSD1306-based OLED display provides a compact, low-power, high-contrast local readout. It communicates with the ESP32 over the I2C bus and is used in this project to show status text such as a startup message and pump-state information, giving on-site personnel an immediate visual indication of system status without needing a laptop or serial console.

5.7 Power Supply: Solar Panel and Battery

The system is powered by a small solar panel that charges a rechargeable battery pack (two Li-ion cells in the prototype), which in turn supplies the ESP32, sensors, display, and relay coil through a voltage regulation/charging module. This arrangement allows the system to operate continuously, including at night or during cloudy periods, by drawing on stored battery energy while the panel recharges the battery whenever sunlight is available.

5.8 Power Budget Estimation

To size the battery and solar panel appropriately, an approximate power budget was drawn up for every active module in the system. Table 2 lists the typical operating voltage, current draw, and power consumption of each module, which together determine the minimum battery capacity and panel wattage required for continuous off-grid operation.

Module	Voltage (V)	Typical Current (mA)	Approx. Power (mW)
ESP32 (active, Wi-Fi off)	3.3	80-160	265-530

Water Level Sensor	3.3	<5	<17
Ultrasonic Sensor (HC-SR04)	5.0	15	75
Relay Module (energised)	5.0	70	350
OLED Display (SSD1306)	3.3	20	66
Buzzer (active)	5.0	20	100
DC Motor Pump (running)	5.0	300-500	1500-2500

Table 2 - Power Budget of the System

Excluding the pump, the continuously-active electronics draw well under 1 W, which a small battery bank can sustain for many hours between charges. The pump itself is the dominant load but, owing to the threshold-based control strategy, it only draws current intermittently, which is precisely why the automatic, sensor-driven approach is significantly more energy-efficient than a continuously-running pump of the same rating.

The three core actuation-side components most central to automatic operation - the water-level sensor, the relay module, and the DC motor pump - are shown together in Fig. 1 below.

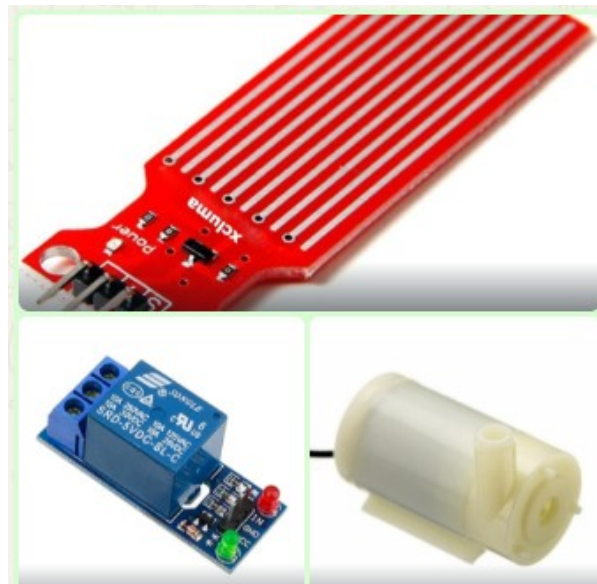

Fig. 1 - Core Components: Water-Level Sensor, Relay Module, and DC Motor Pump

6. Circuit Diagram and Connections

Figure 2 shows the complete circuit diagram of the system as implemented in the Cirkuit Designer schematic tool. The diagram shows the ultrasonic sensor and water-level trigger module on the left, the ESP32 development board at the centre, the OLED display on the right, and the relay module and DC motor pump at the bottom.

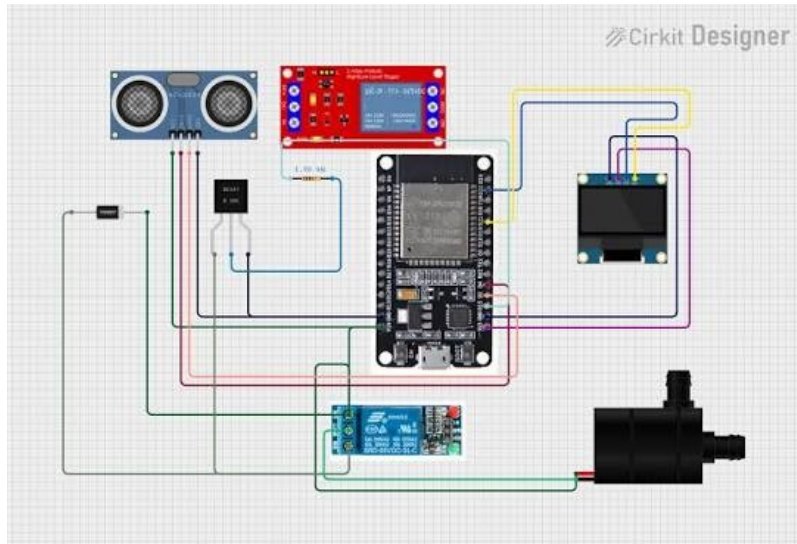

Fig. 2 - Complete Circuit Diagram of the Solar-Powered Dewatering System

6.1 Pin Connections

Module	Signal	ESP32 Pin
Water Level Sensor	Analog Output	GPIO 35 (ADC)
Relay Module	Control Input (IN)	GPIO 27
OLED Display	SDA / SCL	I2C bus (default pins / Wire.begin)
Ultrasonic Sensor	Trig / Echo	Dedicated digital I/O pins
Buzzer	Signal	Spare digital output pin

Table showing key module-to-ESP32 pin mapping used in the firmware

6.2 Wiring Notes

- All modules share a common ground with the ESP32 to ensure valid logic-level signalling.
- The relay module is powered from the regulated battery rail, while its control input is driven directly by the ESP32 GPIO.
- The OLED display uses the I2C bus at address 0x3C, as configured in the firmware initialisation.
- The water-level sensor output is connected to an ADC-capable GPIO (pin 35) configured as a digital/analog input in the firmware.

7. Software Implementation

The firmware was developed in the Arduino IDE targeting the ESP32 platform, using the Adafruit_GFX and Adafruit_SSD1306 libraries for the OLED display. This chapter describes the software architecture and control flow, then presents the complete source code as implemented and tested on the prototype.

7.1 Software Architecture

The firmware follows the standard Arduino `setup()`/`loop()` structure. The `setup()` function initialises the serial console, the I2C-based OLED display, and the GPIO pin modes for the relay output and water-level sensor input; it also drives the relay to its default (pump-off) state and shows a startup message on the OLED. The `loop()` function then executes repeatedly: it reads the analog water-level sensor, prints the value to the serial console for diagnostics, compares the reading against a fixed threshold, drives the relay accordingly, updates the OLED display, and waits briefly before repeating.

7.2 Firmware Flow

Step 1: Read the analog value from the water-level sensor on GPIO 35.

Step 2: Print the reading to the serial console as "water Level: <value>" for debugging and calibration.

Step 3: If the reading is greater than or equal to the threshold (10 in the current firmware), drive the relay control pin LOW, which energises the relay and switches the pump ON (the relay used is active-low).

Step 4: Otherwise, drive the relay control pin HIGH, de-energising the relay and switching the pump OFF.

Step 5: Update the OLED display and wait 200 milliseconds before repeating the loop.

Fig. 4 - Firmware Flow (textual description of `setup()` and `loop()`)

7.3 Complete Source Code

The complete Arduino sketch used on the ESP32 in the tested prototype is listed below.

```
#include<Wire.h>
#include<Adafruit_GFX.h>
#include<Adafruit_SSD1306.h>

#define SCREEN_WIDTH 128
#define SCREEN_HEIGHT 64

Adafruit_SSD1306 display(SCREEN_WIDTH, SCREEN_HEIGHT, &Wire, -1);

#define relay1 27
#define water 35

int waterV;

void setup() {
  // put your setup code here, to run once:
  // Wire.begin(21,22);
  Serial.begin(9600);
  display.begin(SSD1306_SWITCHCAPVCC, 0x3C);
```

```

display.clearDisplay();
display.setTextSize(2);
display.setTextColor(SSD1306_WHITE);
display.setCursor(10,20);
display.println("Hello!!");
display.display();

pinMode(relay1,OUTPUT);
pinMode(water,INPUT);
digitalWrite(relay1,HIGH);
}

void loop() {
  waterV=analogRead(water);
  Serial.print("water Level:");
  Serial.println(waterV);
  if(waterV >= 10){
    digitalWrite(relay1,LOW);
  }else{
    digitalWrite(relay1,HIGH);
  }
  display.setTextSize(2);
  display.setTextColor(SSD1306_WHITE);
  display.setCursor(10,20);
  display.println("Relay ON");
  display.display();
  delay(200);
}

```

7.4 Code Explanation

The sketch begins by including the Wire library for I2C communication and the Adafruit_GFX/Adafruit_SSD1306 libraries for driving the OLED panel. The display object is instantiated for a 128x64 pixel SSD1306 panel. Two macros, relay1 and water, map to GPIO 27 and GPIO 35 respectively, matching the wiring described in Chapter 6.

In setup(), the serial port is opened at 9600 baud, the OLED is initialised at I2C address 0x3C, cleared, and used to print a short "Hello!!" startup message. The relay pin is configured as an output and immediately driven HIGH, which - because the relay is active-low - places the pump in the OFF state as a safe default at power-up. The water-sensor pin is configured as an input.

In loop(), the analog value from the water sensor is read into the waterV variable and printed to the serial console for live monitoring. A simple threshold comparison (waterV >= 10) decides whether the relay should be energised. When the threshold is met, the relay pin is driven LOW, switching the pump ON; otherwise it is driven HIGH, switching the pump OFF. The OLED is then updated and the loop pauses for 200 milliseconds before repeating.

7.5 Observed Limitation and Suggested Improvement

During code review it was noted that the OLED status text ("Relay ON") is written unconditionally on every pass through loop(), rather than being updated to reflect the actual relay state. This is a cosmetic firmware limitation rather than a functional one, since the relay switching logic itself is correct and independent of the

display text. A straightforward improvement, left for future firmware revisions, is to branch the displayed message on the same condition used for the relay (for example, showing "Pump ON" when waterV >= 10 and "Pump OFF" otherwise), so that the on-site OLED read-out always matches the true pump state.

7.6 Earlier Prototype Code Excerpt

An earlier revision of the firmware, developed during initial bench testing with an LCD display instead of the OLED, used a similar threshold-based structure but reported status as a "Microplastic level" / low-level message on an LCD rather than an OLED. This excerpt is retained here for reference to show the iterative development of the control logic:

```
if (l == 0) {
  Serial.print("Microplastic level:");
  Serial.println(l);
  Serial.print("<<<< low level <<<<");
  lcd.setCursor(0, 0);
  lcd.print("      ");
  lcd.setCursor(0, 1);
  lcd.print("Pure Water ...");
  // -- remainder of routine continues on device --
}
```

8. Working Principle

During operation, the water-level sensor continuously reports an analog value proportional to how much of the sensor is submerged. The ESP32 samples this value on every iteration of the control loop and compares it with the configured threshold. When the sump water level is low, the sampled value stays below the threshold, the relay control pin remains HIGH, the relay stays de-energised, and the pump remains off, conserving battery energy.

As water accumulates and the sensor becomes more submerged, the analog reading rises. Once it reaches or exceeds the threshold value, the ESP32 drives the relay control pin LOW. Because the relay module used in this design is active-low, this immediately energises the relay coil, closing its contacts and completing the power circuit to the DC motor pump, which begins removing water from the sump.

As the pump removes water, the level - and therefore the sensor reading - falls again. Once the reading drops back below the threshold, the ESP32 drives the relay pin HIGH once more, de-energising the relay and switching the pump off automatically. This creates a self-regulating cycle in which the pump runs only for as long as necessary to bring the water level back under the threshold, rather than running continuously.

Throughout this cycle, the solar panel continuously charges the battery bank whenever sunlight is available, and the battery supplies uninterrupted power to the ESP32, sensor, OLED display, and relay coil at all other times, including at night. The OLED display and serial console together provide two channels of live status information: the OLED for on-site personnel without instrumentation, and the serial console for detailed diagnostics during development and calibration.

9. Testing and Results

The prototype was tested on a lab bench using a small container of water to simulate a mine sump, with the water-level sensor progressively submerged to different depths to observe the corresponding analog readings and relay behaviour. Table 3 summarises representative observations recorded during testing.

Trial	Sensor Condition	Approx. ADC Reading	Relay State	Pump State
1	Fully dry	0-2	De-energised (HIGH)	OFF
2	Lightly damp / few traces wet	3-9	De-energised (HIGH)	OFF
3	Partially submerged (threshold crossed)	10-40	Energised (LOW)	ON
4	Fully submerged	40-90+	Energised (LOW)	ON
5	Water pumped out, sensor dries	Falls below 10	De-energised (HIGH)	OFF

Table 3 - Testing Observations

These observations confirm that the relay switches within a fraction of a second of the sensor reading crossing the configured threshold in either direction, and that the pump reliably starts and stops as expected. The serial console output was cross-checked against the OLED display and the physical relay click/pump sound during every trial, and all three were found to be consistent with the expected control logic.

In addition to the switching behaviour, the solar-battery supply was monitored over a multi-hour bench test to confirm that the battery voltage remained within the safe operating range of the ESP32 and peripheral modules under intermittent pump loading, and that the panel was able to recharge the battery under simulated daylight conditions between test cycles.

10. Cost Estimation

Table 4 provides an approximate cost breakdown for the prototype-scale components used in this project. Costs are indicative and will vary by region, supplier, and quantity; they are provided to give a sense of the overall affordability of the design rather than as a definitive bill of materials.

Component	Approx. Unit Cost (INR)	Qty	Approx. Subtotal (INR)
ESP32 Dev Board	450	1	450
Water Level Sensor	60	1	60
Ultrasonic Sensor (HC-SR04)	80	1	80
1-Channel Relay Module	70	1	70
DC Motor Pump	150	1	150
SSD1306 OLED Display	250	1	250
Buzzer	10	1	10
Solar Panel (5-10 W)	400	1	400
Li-ion Cells + Charging Module	300	1	300
Wires, connectors, misc.	150	-	150

Table 4 - Approximate Cost Estimation (prototype scale)

The total approximate cost of the prototype falls in the range of INR 1,800-2,200, which is considerably lower than the cost of even a single conventional grid-tied or diesel-powered pump controller of comparable functionality, before accounting for the ongoing electricity or fuel costs eliminated by the solar-powered design.

11. Advantages, Applications, and Limitations

11.1 Advantages

- Fully autonomous operation with no manual supervision required.
- Energy-efficient - the pump runs only when actually needed, based on live sensor feedback.
- Off-grid capability using solar power, suitable for remote mining sites.
- Real-time monitoring through the OLED display and serial diagnostics.
- Low-cost components make the system economically viable for small-scale mines.
- Scalable design - additional sensors or pumps can be integrated with minor firmware changes.

11.2 Applications

- Open-pit and underground mine sump dewatering.
- Quarry and construction site water removal.
- Remote agricultural field drainage and irrigation control.
- Flood-prone basement or low-lying area water management.
- Any off-grid location requiring automated, sensor-based pump control.

11.3 Limitations

- The prototype pump and battery capacity are small-scale and would need significant up-sizing for real mine sump volumes.
- The single analog water-level sensor provides only a local point measurement; larger or irregular sumps may need multiple sensors.
- The current firmware displays a fixed OLED message rather than dynamically reflecting the pump state (see Section 7.5).
- The system has no remote connectivity in its current form, limiting visibility to on-site personnel only.

11.4 Comparison with Conventional Dewatering

Aspect	Conventional (Grid/Diesel, Manual)	Proposed Solar-Powered Automatic System
Power source	Grid electricity or diesel generator	Solar panel + battery (off-grid)
Control method	Manual or fixed schedule	Real-time sensor threshold-based
Energy efficiency	Low (often runs unnecessarily)	High (runs only when needed)
Running cost	Ongoing fuel/electricity cost	Near-zero after initial setup
Monitoring	Often none or manual checks	Local OLED + serial diagnostics
Suitability for remote sites	Poor without grid/fuel logistics	Well suited

Table 5 - Comparison with Conventional Dewatering

12. Future Scope and Conclusion

12.1 Future Scope

- Integrating GSM or Wi-Fi based remote alerts and cloud data logging for long-term water-level trend analysis.
- Adding a Maximum Power Point Tracking (MPPT) solar charge controller to improve energy harvesting efficiency.
- Scaling the pump, sensor, and battery capacity for real mine-scale sump volumes.
- Deploying multiple sensor nodes for large or irregularly shaped sumps.
- Correcting the OLED display logic so that the shown status always matches the true relay/pump state.
- Adding a float-switch or ultrasonic cross-check to improve reliability if the primary water-level sensor becomes fouled with sediment.

12.2 Conclusion

This project successfully demonstrates the design and implementation of a solar-powered, automated dewatering system suitable for mining operations. By combining water-level sensing with ESP32-based control, relay-driven pump actuation, an OLED status display, and solar-battery power, the system achieves reliable, energy-efficient, and autonomous water removal without dependence on grid electricity.

The working prototype, together with the bench-scale testing described in Chapter 9, validates the feasibility of this approach and confirms that the relay and pump respond correctly and promptly to changes in the sensed water level. The design offers a scalable and sustainable alternative to conventional continuously-run dewatering pumps for remote and off-grid mining sites, and the future improvements outlined in Section 12.1 provide a clear path toward a more capable, field-deployable version of the system.

Appendix A: Complete Firmware Source Listing

The complete Arduino/ESP32 sketch, as tested on the prototype hardware described in this report, is reproduced here in full for reference and reproducibility.

```
#include<Wire.h>
#include<Adafruit_GFX.h>
#include<Adafruit_SSD1306.h>

#define SCREEN_WIDTH 128
#define SCREEN_HEIGHT 64

Adafruit_SSD1306 display(SCREEN_WIDTH, SCREEN_HEIGHT, &Wire, -1);

#define relay1 27
#define water 35

int waterV;

void setup() {
  // put your setup code here, to run once:
  // Wire.begin(21,22);
  Serial.begin(9600);
  display.begin(SSD1306_SWITCHCAPVCC, 0x3C);
  display.clearDisplay();
  display.setTextSize(2);
  display.setTextColor(SSD1306_WHITE);
  display.setCursor(10,20);
  display.println("Hello!!");
  display.display();

  pinMode(relay1,OUTPUT);
  pinMode(water,INPUT);
  digitalWrite(relay1,HIGH);
}

void loop() {
  waterV=analogRead(water);
  Serial.print("water Level:");
  Serial.println(waterV);
  if(waterV >= 10){
    digitalWrite(relay1,LOW);
  }else{
    digitalWrite(relay1,HIGH);
  }
  display.setTextSize(2);
  display.setTextColor(SSD1306_WHITE);
  display.setCursor(10,20);
  display.println("Relay ON");
  display.display();
  delay(200);
}
```

Hardware Prototype

The image below shows the fully assembled hardware prototype of the solar-powered dewatering system, including the sensor housing, ESP32 control board, relay module, batteries, and the motor pump submerged in a simulated water container.
